Chapter 1

Theoretical background

In this chapter we will provide the necessary background for the user to understand the mechanisms used later in the paper. The description of the following systems is a brief introduction, intended to familiarize the reader with concepts that are fundamental for the methods presented.

Specifically, section 1.1 describes the functionality of the gzip compression method and the algorithms that it entails. Section 1.2 covers the same-origin policy that applies in the web application security model. In section 1.3 we explain the Transport Layer Security, which is the main protocol used today to provide communications security over the Internet. Finally, in section 1.4 we describe attack methodologies in order for an adversary to perform a Man-in-the-middle attack, such as ARP spoofing and DNS poisoning.

1.1   gzip

gzip is a software application used for file compression and decompression. It is the most used encryption method on the Internet, integrated in protocols such as the Hypertext Transfer Protocol (HTTP), the Extensible Messaging and Presence Protocol (XMPP) and many more. Derivatives of gzip include the tar utility, which can extract .tar.gz files, as well as zlib, an abstraction of the DEFLATE algorithm in library form.[1]

It is based on the DEFLATE algorithm, which is a combination of LZ77 and Huffman coding. DEFLATE could be described by the following encryption schema:

$DEFLATE(m) = Huffman(LZ77(m))$

In the following sections we will briefly describe the functionality of both these compression algorithms.

1.1.1   LZ77

LZ77 is a lossless data compression algorithm published in paper by A. Lempel and J. Ziv in 1977. [6] It achieves compression by replacing repeated occurences of data with references to a copy of that data existing earlier in the uncompressed data stream. The reference composes of a pair of numbers, the first of which represents the length of the

---

[1] https://en.wikipedia.org/wiki/Gzip

repeated portion, while the second describes the distance backwards in the stream, until the beginning of the portion is met. In order to spot repeats, the protocol needs to keep track of some amount of the most recent data, specifically the latest 32 Kb. This data is held in a sliding window, so in order for a portion of data to be compressed, the initial appearance of this repeated portion needs to have occurred at most 32 Kb up the data stream. Also, the minimum legth of a text to be compressed is 3 characters, while compressed text can also have literals as well as pointers.

Below you can see an example of a step-by-step execution of the algorithm for a specific text:

Hello, world! I love you.
Hello, world! I hate you.
Hello, world! Hello, world! Hello, world!

Figure 1.1: First we get the plaintext to be compressed.

Hello, world! I love you.

Hello, world! I love you.

Figure 1.2: Compression starts with literal representation.

Hello, world! I love you.
Hello, world! I

Hello, world! I love you.
(26, 16)

Figure 1.3: We then use a pointer at distance 26 and length 16.

Hello, world! I love you.
Hello, world! I hate

Hello, world! I love you.
(26, 16)   hate

Figure 1.4: We continue with literal.

Hello, world! I love you.

Hello, world! I hate you.

Hello, world!

Hello, world! I love you.

⌐(26, 16)   hate ⌐(21, 5)

⌐(26, 14)

Figure 1.5: We use a pointer pointing to a pointer.

Hello, world! I love you.

Hello, world! I hate you.

Hello, world! Hello world!

Hello, world! I love you.

⌐(26, 16)   hate (21, 5)

⌐(26, 14) (14, 14)

Figure 1.6: We then use a pointer pointing to a pointer pointing to a pointer.

Hello, world! I love you.

Hello, world! I hate you.

Hello, world! Hello world! Hello world!

Hello, world! I love you.

⌐(26, 16)   hate ⌐(21, 5)

⌐(26, 14) (14, 28)

Figure 1.7: Finally, we use a pointer pointing to itself.

1.1.2 Huffman coding

Huffman coding is also a lossless data compression algorithm developed by David A. Huffman and published in 1952. [3] When compressing a text, a variable-length code table is created to map source symbols to bitstreams. Each source symbol can be of less or more bits than originally and the mapping table is used to translate source symbols into bitstreams during compression and vice versa during decompression. The mapping table could be represented by a binary tree of nodes. Each leaf node represents a source symbol, which can be accessed from the root by following the left path for 0 and the right path for 1. Each source symbol can be represented only by leaf nodes, therefore the code is prefix-free, meaning no bitstream representing a source symbol can be the prefix of any other bitstream representing a different source symbol. The final mapping of source symbols to bistreams is calculated by finding

the frequency of appearance for each source symbol of the plaintext. That way, most common symbols can be coded in shorter bitstreams, thus compressing the initial text.

Below follows an example of a plaintext and a valid Huffman tree for compressing it:

Chancellor on bring of second bailout for banks [2]

Frequency Analysis

o: 6	**n**: 5	**r**: 3	**l**: 3
b: 3	**c**: 3	**a**: 3	**s**: 2
k: 2	**e**: 2	**i**: 2	**f**: 2
h: 1	**d**: 1	**t**: 1	**u**: 1

h: 1111001	**d**: 1111010	**t**: 1111011	**u**: 1111100

Initial text size: 320 bits
Compressed text size: 167 bits

1.2 Same-origin policy

Same-origin policy is an important aspect of the web application security model. According to that policy, a web browser allow scripts contained in one page to access data in a second page only if both pages have the same *origin*. Origin is defined as the combination of Uniform Resource Identifier scheme, hostname and port number. For example, a document retrieved from the website *http://example.com/target.html* is not allowed under the same-origin policy to access the Document-Object Model of a document retrieved from *https://head.example.com/target.html*, since the two websites have different URI schema (*http* vs *https*) and different hostname (*example.com* vs *head.example.com*).

Same-origin policy is particularly important in modern web applications, that rely greatly on HTTP cookies to maintain authenticated sessions. If same-origin policy was not implemented the data confidentiality and integrity of cookies, as well as every other content of web pages, would have been compromised. However, despite the application of same-origin policy by modern browsers, there exist attacks that enable an adversary to bypass it and breach a user's communication with a website. Two such major types of vulnerabilities, cross-site scripting and cross-site request forgery are described in the following subsections.

1.2.1 Cross-site scripting

Cross-site scripting (XSS) is a security vulnerability that allows an adversary to inject client-side script into web pages viewed by other users. That way, same-origin policy

---

[2] https://en.bitcoin.it/wiki/Genesis_block

can be bypassed and sensitive data handled by the vulnerable website may be compromised. XSS could be divided into two major types, *non-persistent* and *persistent* [3], which we will describe below.

Non-persistent XSS vulnerabilities are the most common. They show up when the web server does not parse the input in order to escape or reject HTML control characters, allowing for scripts injected to the input to run unnoticeable. Usual methods of performing non-persistent XSS include mail or website url links and search requests.

Persistent XSS occurs when data provided by the attacker are stored by the server. Responses from the server to different users will then include the script injected from the attacker, allowing it to run automatically on the victim's browsers without needing to target them individually. An example of such attack is when posting texts on social networks or message boards.

1.2.2 Cross-site request forgery

Cross-site request forgery (CSRF) is an exploit that allows an attacker to issue unauthorized commands to a website, on behalf of a user the website trusts. Hence the attacker can forge a request to perform actions or post data on a website the victim is logged in, execute remote code with root privileges or compromise a root certificate, resulting in a breach of a whole public key infrastructure (PKI).

CSRF can be performed when the victim is trusted by a website and the attacker can trick the victim's browser into sending HTTP requests to that website. For example, when a Alice visits a web page that contains the HTML image tag *<img src="`http://bank.example.com/withdraw?account=Alice&amount=1000000&for=Mallory`">* [4] that Mallory has injected, a request from Alice's browser to the example bank's website will be issued, stating for an amount of 1000000 to be transfered from Alice's account to Mallory's. If Alice is logged in the example bank's website, the browser will include the cookie containing Alice's authentication information in the request, making it a valid request for a transfer. If the website does not perform more sanity checks or further validation from Alice, the unauthorized transaction will be completed. An attack such as this is very common on Internet forums that allow users to post images.

A method of mitigation of CSRF is a Cookie-to-Header token. The web application sets a cookie that contains a random token that validates a specific user session. Javascript on client side reads that token and includes it in a HTTP header sent with each request to the web application. Since only Javascript running within the same origin will be allowed to read the token, we can assume that it's value is safe from unauthorized scripts to read and copy it to a custom header in order to mark a rogue request as valid.

1.3 Transport Layer Security

Transport Layer Security (TLS) is a protocol that provides communications security over the internet, allowing a server and a client to communicate in a way that prevents eavesdropping, tampering or message forgery. [2]

---

[3] `https://en.wikipedia.org/wiki/Cross-site_scripting`
[4] `https://en.wikipedia.org/wiki/Cross-site_request_forgery`

The users negotiate a symmetric key via assymetric cryptography that is provided by X.509 certificates, therefore there exist certificate authorities and a public key infrastructure (PKI), in order for the certificates to be verified for their owners. However, it can be understood that, due to their key role, certificate authorities are points of failure in the system, enabling for Man-in-the-Middle attacks, in a case when an adversary has managed to forge a root certificate.

Apart from certificate-related attacks, a well-known category is compression attacks. [5] Such attacks exploit TLS-level compression so as to decrypt ciphertext. In this document, we investigate the threat model and performance of such an attack, BREACH.

In the following subsections we will briefly describe some of the protocol details, especially handshake and the format of TLS records.

1.3.1 TLS handshake
Figure 1.8: TLS handshake flow.

---

[5] https://tools.ietf.org/html/rfc7457

This sequence diagram presents the functionality of TLS handshake. User and server exchange the basic parameters of the connection, specifically the protocol version, cipher suite, compression method and random numbers, with the ClientHello and ServerHello records. The server then provides all information needed from the user to validate and use the asymmetric server key, in order to compute the symmetric key to be used in the rest of the communication. The client computes a *PreMasterKey*, that is sent to the server, which is used by both parties to compute the symmetric key. Finally, both sides exchange and validate hash and MAC over the previous messages, after which they both have the ability to communicate safely.

The above flow describes the basic TLS handshake. Client-authenticated and resumed handshakes have similar functionality, which are not relevant for the purpose of this paper.

1.3.2 TLS record

+	Byte +0	Byte +1	Byte +2	Byte +3
Byte 0	Content type			
Bytes 1..4	Version		Length	
	(Major)	(Minor)	(bits 15..8)	(bits 7..0)
Bytes 5..(*m*-1)	Protocol message(s)			
Bytes *m*..(*p-1*)	MAC (optional)			
Bytes *p*..(*q-1*)	Padding (block ciphers only)			

Figure 1.9: TLS record.

The above figure [6] depicts the general format of all TLS records.

The first field describes the Record Layer Protocol Type contained in the record, which can be one of the following:

Hex	Type
0x14	ChangeCipherSpec
0x15	Alert
0x16	Handshake
0x17	Appliation
0x18	Heartbeat

The second field defines the TLS version for the record message, which is identified my the major and minor version as below:

---

[6] https://en.wikipedia.org/wiki/Transport_Layer_Security

Major	Minor	Version
3	0	SSL 3.0
3	1	TLS 1.0
3	2	TLS 1.1
3	3	TLS 1.2

The length of the contained record message, MAC and padding is then calculated by the following two fiels as: $256 * (bits15..8) + (bits7..0)$.

Finally, the payload of the record, which, depending on the type, may be encrypted, the MAC, if provided, and the padding, if needed, make up the rest of the TLS record.

1.4 Man-in-the-Middle

Man-in-the-Middle (MitM) is one of the most common attack vectors, where an attacker reroutes the communication of two parties, in order to be controlled and possibly altered. The aggressiveness of the attack can vary from passive eavesdropping to full control of the communication, as long as the attacker is able to impersonate both parties and convince them to be trusted.

Figure 1.10: Man-in-the-Middle.

MitM attacks can be mitigated by using end-to-end cryptography, mutual authentication or PKIs. However, some attacks manage to bypass such mitigation techniques. Below, we descripe two such attacks, ARP Spoofing and DNS cache poisoning.

1.4.1 ARP Spoofing

ARP spoofing

[7] is a technique where an attacker sends Address Resolution Protocol (ARP) messages over the network, so as to assosiate the MAC address with the IP address of another host. That way, the attacker may intercept the traffic of the network, modify or deny packets, performing denial of service, MitM or session hijacking attacks.

---

[7] https://en.wikipedia.org/wiki/ARP_spoofing
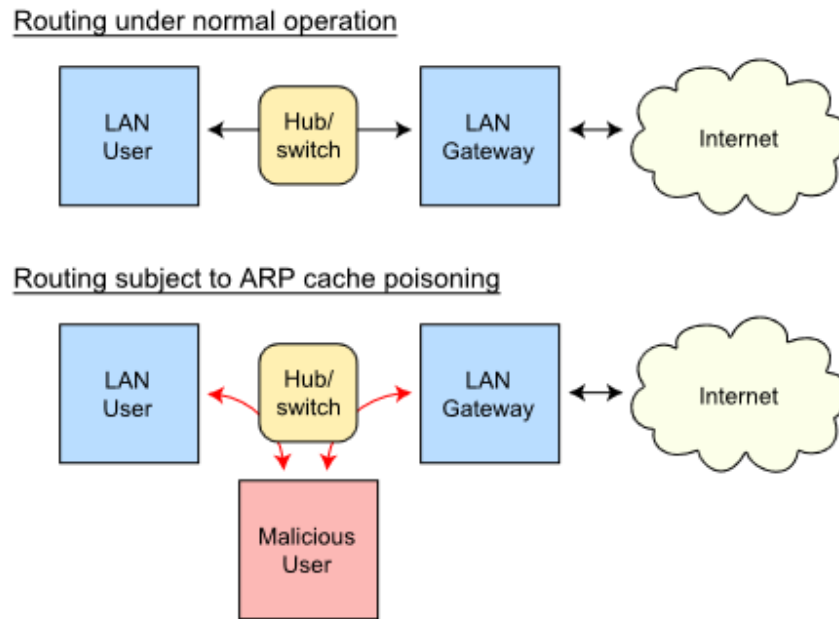

Figure 1.11: Arp Spoofing.

ARP spoofing can be also used for legitimate reasons, when a developer needs to debug IP traffic between two hosts. That way, the developer can act as proxy between the two hosts or configure the switch that is normally used by the two parties to forward traffic for monitoring.

1.4.2 DNS spoofing
Figure 1.12: DNS Spoofing.

DNS spoofing (or DNS cache poisoning) is an attack, when the adversary introduces data into a Domain Name System resolver's cache, in order to return an incorrect address for a specific host.

DNS servers are usually provided by Internet Service Providers (ISPs), used to resolve IP addresses to human-readable hostnames faster. A malicious employee, or anyone that has gained unauthorized access to the server, can then perform DNS poisoning, affecting every user that is being serviced by that server.

Chapter 2

Partially Chosen Plaintext Attack

Traditionally, cryptographers have used games for security analysis. Such games include the indistinguishability under chosen-plaintext-attack (IND-CPA), the indistinguishability under chosen ciphertext attack/adaptive chosen ciphertext attack (IND-CCA1, IND-CCA2) etc [1]. In this chapter, we introduce a definition for a new property of encryption schemes, called indistinguishability under partially-chosen-plaintext-attack (IND-PCPA). We will also show provide comparison between IND-PCPA and other kwown forms of cryptosystem properties.

2.1 Partially Chosen Plaintext Indistinguishability

2.1.1 Definition

IND-PCPA uses a definition similar to that of IND-CPA. For a probabilistic asymmetric key encryption algorithm, indistinguishability under partially chosen plaintext attack (IND-PCPA) is defined by the following game between an adversary and a challenger.

- The challenger generates a pair P_k, S_k and publishes P_k to the adversary.

- The adversary may perform a polynomially bounded number of encryptions or other operations.

- Eventually, the adversary submits two distinct chosen plaintexts M_0, M_1 to the challenger.

- The challenger selects a bit $b \in 0, 1$ uniformly at random.

- The adversary can then submit any number of selected plaintexts $R_i, i \in N, |R| \geq 0$, so the challenger sends the ciphertext $C_i = E(P_k, M_b||R_i)$ back to the adversary.

- The adversary is free to perform any number of additional computations or encryptions, before finally guessing the value of b.

A cryptosystem is indistinguishable under partially chosen plaintext attack, if every probabilistic polynomial time adversary has only a negligible advantage on finding b over random guessing. An adversary is said to have a negligible advantage if it wins

---

[1] https://en.wikipedia.org/wiki/Ciphertext_indistinguishability

the above game with probability $\frac{1}{2} + \epsilon(k)$, where $\epsilon(k)$ is a negligible function in the security parameter k.

Intuitively, we can think that the adversary has the ability to modify the plaintext of a message, by appending a portion of data of his own choice to it, without knowledge of the plaintext itself. He can then acquire the ciphertext of the modified text and perform any kinds of computations on it. A system could then be described as IND-PCPA, if the adversary is unable to gain more information about the plaintext, than he could by guessing at random.

2.1.2 IND-PCPA vs IND-CPA

Suppose the adversary submits the empty string as the chosen plaintext, a choice which is allowed by the definition of the game. The challenger would then send back the ciphertext $C_i = E(P_k, M_b || "") = E(P_k, M_b)$, which is the ciphertext returned from the challenger during the IND-CPA game. Therefore, if the adversary has the ability to beat the game of IND-PCPA, i.e. if the system is not indistinguishable under partially chosen plaintext attacks, he also has the ability to beat the game of IND-CPA. Thus we have shown that IND-PCPA is at least as strong as IND-CPA.

2.2 PCPA on compressed encrypted protocols

2.2.1 Compression-before-encryption and vice versa

When having a system that applies both compression and encryption on a given plaintext, it would be interesting to investigate the order the transformations should be executed.

Lossless data compression algorithms rely on statistical patters to reduce the size of the data to be compressed, without losing information. Such a method is possible, since most real-world data has statistical redundancy. However, it can be understood from the above that such compression algorithms will fail to compress some data sets, if there is no statistical pattern to exploit.

Encryption algorithms rely on adding entropy on the ciphertext produced. If the ciphertext contains repeated portions or statistical patterns, such behaviour can be exploited to deduce the plaintext.

In the case that we apply compression after encryption, the text to be compressed should demostrate no statistical analysis exploits, as described above. That way compression will be unable to reduce the size of the data. In addition, compression after encryption does not increase the security of the protocol.

On the other hand, applying encryption after compression seems a better solution. The compression algorithm can exploit the statistical redundancies of the plaintext, while the encryption algorithm, if applied perfectly on the compressed text, should produce a random stream of data. Also, since compression also adds entropy, this scheme should make it harder for attackers who rely on differential cryptanalysis to break the system.

2.2.2   PCPA scenario on compression-before-encryption protocol

Let's assume a system that composes encryption and compression in the following manner:

$$c = Encrypt(Compress(m))$$

where c is the ciphertext and m is the plaintext.

Suppose the plaintext contains a specific secret, among random strings of data, and the attacker can issue a PCPA with a chosen plaintext, which we will call reflection. The plaintext then takes the form:

$$m = n_1 || secret || n_2 || reflection || n_3$$

where n_1, n_2, n_3 are random nonces.

If the reflection is equal to the secret, the compression mechanism will recognize the pattern and compress the two portions. In other case, the two strings will not demonstrate any statistical redundancy and compression will perform worse. As a result, in the first case the data to be encrypted will be smaller than in the second case.

Most commonly encryption is done by a stream or a block cipher. In the first case, the lengths of a plaintext and the corresponding ciphertext are identical, whereas in the second case they differ by the number of the padding bits, which is relatively small. That way, in the above case, an adversary could identify a pattern and extract information about the plaintext, based on the lengths of the two ciphertexts.

2.3   Known PCPA exploits

2.3.1   CRIME

"Compression Ratio Info-leak Made Easy" (CRIME) [4] is a security exploit that was revealed at the 2012 ekoparty. As described, "it decrypts HTTPS traffic to steal cookies and hijack sessions".

In order for the attack to succeed, there are two requirements. Firstly, the attacker should be able to sniff the victim's network, so as to see the request/response packet lengths. Secondly, the victim should visit a website controlled by the attacker or surf on non-HTTPS sites, in order for the CRIME JavaScript to be executed.

If the above requirements are met, the attacker makes a guess for the secret to be stolen and asks the browser to send a request with this guess as the path. The attacker can then observe the length of the request and, if the length is less than usual, it is assumed that the guess string was compressed with the secret, so it was correct.

CRIME has been mitigated by disabling TLS and SPDY compression on both Chrome and Firefox browsers, as well as various server software packages. However, HTTP compression is still supported, while some web servers that still support TLS compression are also vulnerable.

2.3.2 BREACH

"Browser Reconnaissance and Exfiltration via Adaptive Compression of Hypertext" (BREACH) [5] is a security exploit built based on CRIME. Presented at the August 2013 Black Hat conference, it targets the size of compressed HTTP responses and extracts secrets hidden in the response body.

Like the CRIME attack, the attacker needs to sniff the victim's network traffic, as well as force the victim's browser to issue requests on the chosen endpoint. Additionally, the original attack works against stream ciphers only, it assumes zero noise in the response, as well as a known prefix for the secret, although a solution would be to guess the first two characters of the secret, in order to bootstrap the attack.

From then on, the methodology is the same in general as CRIME's. The attacker guesses a value, which is then included in the response body along with the secret and, if correct, it is compressed well with it, resulting in smaller response length.

BREACH has not yet been fully mitigated, although Gluck, Harris and Prado proposed various counter measures for the attack. We will investigate these mitigation techniques in depth in Chapter **??**.

Chapter 3

Attack Model

In this chapter, we will extensively present the threat model of BREACH. We will explain the conditions that should be met so as to launch the attack and describe our code implementation for that case. Also, we will investigate the types of vulnerabilities in web applications that can be exploited with this attack, as well as introduce alternative secrets, that have not been taken into consideration before.

3.1 Mode of Operation

3.1.1 Description

The first step of the attack is for the attacker to gain control of the victim's network, specifically being aple to view the victim's encrypted traffic. This can be accomplished using the Man-in-the-Middle techniques described in Section 1.4.

After that the BREACH JavaScript that issues the requests needs to be executed from the victim's browser. The first way to do this is to persuade the victim to visit a website where the js runs, usually with social engineering methods, such as phishing or spam email. Another way would be for the attacker to inject the js code in a request made to a regular HTTP website. The following figure depicts this methodology, which is based on the fact that regular HTTP traffic is not encrypted and also does not ensure data integrity.

Figure 3.1: JavaScript injection.

The script issues multiple requests to the target endpoint, which are sniffed by the attacker. As described in Section 1.2 the attacker cannot read the plaintext response, however the length of both the request and the response is visible on the network.

Each request contains some data, that is reflected in the response. Since the victim is logged in the target endpoint website, the response body will also contain the secrets. If the conditions defined in Section 1.1.1 are met, the secret and the reflected attacker input will be compressed and encrypted.

By issuing a large amount of requests for different inputs, the attacker can analyze the response lengths and extract information about the plaintext secrets, as described above.

3.1.2   Man-in-the-Middle implementation

In order to gain control of the victim's traffic towards a chosen endpoint, we created a Python script that performs a Man-in-the-Middle. For the purpose of this paper, the 'hosts' file of the test machine was configured to redirect traffic regarding the chosen endpoint towards localhost, as shown below:

```
127.0.0.1 localhost
127.0.1.1 debian.home debian

# The following lines are desirable for IPv6 capable hosts
::1     localhost ip6-localhost ip6-loopback
ff02::1 ip6-allnodes
ff02::2 ip6-allrouters

# BREACH Targets

127.0.0.1 mail.google.com
```

Listing 3.1: Test machine hosts file

The user can set the IPs and ports of the victim and the endpoint, in order for the Python script to open TCP sockets on both directions, so that traffic from the victim to the endpoint and vice versa is routed through the Man-in-the-Middle implementation.

After the environment is set, the script performs an infinite loop, where the 'select' module of Python is used to block the script until a packet is received on either of the sockets.

If a packet is received, the socket over which it was received can identify the source of the data. In either case, the packet is parsed in order to log the TLS header and the payload, after which it is forwarded to the appropriate destination.

The parser is vital, since header contains information regarding the version of TLS used, as well as the length of the packet. For that purpose, we have created a mechanism to perform packet defragmentation, since a TLS record can span over multiple TCP packets.

Finally, a TLS downgrade attack mechanism is also implemented. In such case, the Client Hello packet is intercepted and dropped, while the MitM sends as a response a fatal 'HANDSHAKE FAILURE' alert to the victim.

The victim's browser is usually configured to attempt a connection with a lower TLS version, where it should also include the "TLS_FALLBACK_SCSV" option in the cipher suite list. If the server is configured properly, the downgrade attempt should be recognised through the "TLS_FALLBACK_SCSV" and the connection should be dropped. In other case, the TLS version could be downgraded to a point where a less safe connection is established, such as with version SSL 3.0 or using the RC4 stream cipher. For further information on the downgrade vulnerabilities see POODLE [1].

The code described above, as well as the constants library, can be found in Appendix Sections 4.1 and 4.2 respectively.

3.1.3   BREACH JavaScript implementation

For the implementation of the BREACH JavaScript, we assume the user has provided the alphabet that the secret character belongs to, as well as the known prefix needed to bootstrap the attack. This information will be written to a file used by the JavaScript to perform the attack, an example of which is shown below:

```
AF6bup
ladbfsk!1_2_3_4_5_6_7_8_9_AF6bup0znq,ladbfsk!0_2_3_4_5_6_7_8_9_AF6bup1znq
    ,ladbfsk!0_1_3_4_5_6_7_8_9_AF6bup2znq,ladbfsk!0
    _1_2_4_5_6_7_8_9_AF6bup3znq,ladbfsk!0_1_2_3_5_6_7_8_9_AF6bup4znq,
    ladbfsk!0_1_2_3_4_6_7_8_9_AF6bup5znq,ladbfsk!0
    _1_2_3_4_5_7_8_9_AF6bup6znq,ladbfsk!0_1_2_3_4_5_6_8_9_AF6bup7znq,
    ladbfsk!0_1_2_3_4_5_6_7_9_AF6bup8znq,ladbfsk!0
    _1_2_3_4_5_6_7_8_AF6bup9znq
```

Listing 3.2: request.txt

The script then uses the jQuery library [1] to read the info from the file and begin the attack. If the file is corrupted or either of the attack variables has changed, a delay of 10 seconds is introduced, so that the system is balanced. After that, a request for each item of the attack vector is issued serially, continuing from the beginning when the end of the vector is reached.

A delay of 10 seconds is also introduced if the above function fails for any reason, i.e. if the info file does not exist. That way the attack is persistent and it is the frameworks responsibility to provide the JavaScript with a valid information file.

For the purpose of this paper, the script was included in a local minimal HTML web page that was visited in order for the attack to begin. However, with slight modifications, it could be run on real world applications or injected in HTTP responses, as described above.

The BREACH script and the HTML web page can be found in the Appendix Sections 4.3 and 4.4.

3.2   Vulnerable endpoints

In the original BREACH paper [5], Gluck, Harris and Prado investigated the use of CSRF tokens included in HTTP responses as secrets to be stolen with the attack. In this paper

---

[1] http://code.jquery.com/jquery-2.1.4.min.js

we suggest alternative secrets, as well as point out specific vulnerabilities on widely used web applications, such as Facebook and Gmail.

Chapter 4

Appendix

4.1 Man-in-the-Middle library

```
import socket
import select
import logging
import binascii
from os import system, path
import sys
import signal
from io_library import kill_signal_handler, get_arguments_dict,
    setup_logger
import constants

signal.signal(signal.SIGINT, kill_signal_handler)

class Connector():
    '''
    Class that handles the network connection for breach.
    '''
    def __init__(self, args_dict):
        '''
        Initialize loggers and arguments dictionary.
        '''
        self.args_dict = args_dict
        if 'full_logger' not in args_dict:
            if args_dict['verbose'] < 4:
                setup_logger('full_logger', 'full_breach.log', args_dict,
    logging.ERROR)
            else:
                setup_logger('full_logger', 'full_breach.log', args_dict)
